The relationship between renewable energy and retail electricity prices: Panel evidence from OECD countries

A.M. Oosthuizen*, R. Inglesi-Lotz[†] and G.A. Thopil[‡]

September 26, 2019

Abstract

The centrality of electricity to everyday life is indisputable, and the price thereof can have significant implications. Literature is inconclusive over the effect of the renewable energy share in the energy mix on retail electricity price as country-specific regulatory policy has a significant impact on retail electricity prices. The purpose of this paper is to determine the effect of the increasing renewable electricity share on retail electricity prices for 34-OECD countries, considering the change in market structure for 23 EU countries. The results show that the influence of the renewable energy share in the energy mix to retail electricity prices is positive and statistically significant. Increasing renewable sources is inescapable in reaching SDG7, while increased awareness of true price signals should prompt private investment while phasing out support schemes in the long run. A sound regulatory framework is required to account for renewable intermittency as well as effective supply and demand matching. The positive impact on electricity prices should not deter policymakers from promoting renewable energy as the effect is marginal and is expected to decline in coming years, improving energy security. The benefits of employing renewables far outweigh the environmental cost.

Keywords: renewable energy; electricity prices; OECD; energy dependence

1 Introduction

The centrality of electricity to everyday life is indisputable, and the price thereof can have significant implications. The European Commission (2016) states that while low electricity prices "raise purchasing power," and increases both living standards and industry competition, high electricity prices act as a signal to

move to cleaner energy and improve energy efficiency. Studying the effect of increasing renewables on electricity prices is crucial in understanding market signals.

The International Energy Agency (IEA) works along with 26 OECD member countries in co-operation with the European Commission to “improve the world’s energy supply and demand structure by developing alternative energy sources” along with assisting “the integration of environmental and energy policies” (IEA, 2005). Many IEA member countries embarked on the process of electricity market liberalization in the 1990s motivated by sector inefficiencies, the increasing trend of privatizing state-owned companies and the declining transitional cost towards a different system. Electricity market liberalization contributed to significant economic benefits, as competition increased efficiency within the sector, producing long-term consumer benefits. However, the system requires government involvement in upholding checks and balances. (IEA, 2005)

The European Union fully liberalized the majority of their electricity markets in 2014, all member countries except Bulgaria and Malta are compliant. Market liberalization for numerous countries has been in effect for 5 to 10 years, excluding Cyprus who was the last to liberalize (European Commission, 2014). Industry electricity prices decreased in Australia, Denmark, Finland, Norway, Sweden, the United Kingdom, and the United States after market liberalization. However, retail electricity prices have seen an increase, largely due to increasing fuel cost and cost associated with CO₂ emissions within Europe (IEA, 2005). Trujillo-Baute, del Río and Mir-Artigues (2018) attribute the sharp increase in retail electricity prices over the years to the increase in renewable energy sources, while the European Commission (2016) states that wholesale electricity prices have decreased significantly although retail electricity prices tend to increase due to the “network price component, taxes, and levies”. Transmission and distribution networks along with fuel cost are essential components of electricity prices, the former resulting from developments in economic regulation and not from increased competition in the electricity market. Fuel efficiency and ultimately energy efficiency has been a significant risk indicator for investors and determines the economic efficiency of a power plant (IEA, 2005). The International Renewable Energy Agency (IRENA, 2018) recently projected that within the next two years all renewable energy sources would be price competitive with fossil fuels. This new development is likely to increase the renewable energy share even further. The cost of Renewable energy technologies decreased over the years and is expected to decrease further, which could potentially lower electricity prices in the future.

Full market liberalization reduces electricity prices by increasing competition; moreover, the European Union has committed to reducing emissions under the Kyoto protocol and therefore employed renewable energy support schemes to encourage the implementation of renewable technologies (IEA, 2001) (UNFCCC, Kyoto, 11 December 1997). The Paris Agreement reached at the United Nations Framework Convention on Climate Change, Conference of the Parties (COP 21) in 2015 strengthens policies on climate change and incentives the transition towards a low-carbon energy system. The average CO₂ intensity of

electricity needs to decrease by 96% from 2015 to 2050 to prevent global temperatures from increasing with 2°C (UNFCCC, 1997).

Pressures on CO₂ emissions motivated carbon-tax in several OECD member countries, including the European Union implemented in 2003, certain states of the United States, Canada in 2008, South Korea in 2015 and most recently China in 2016 (IEA, 2016). The IEA (2016) states that high carbon prices and increasing shares of RES can generate sufficient revenue to recover the fixed cost of low-carbon power sources, potentially increasing renewable investments. Wholesale electricity prices are decreasing due to the merit-order effect, once the fixed cost of renewable technologies are covered the marginal cost associated are very low and consequently places first in the merit order. The aftermath results in decreased revenue for all operators as well as overcapacity. For effective investment to happen, these issues have to be addressed for the transitional period towards low-carbon technologies. Support policies include fixed-price instruments, shared risk instruments, and subsidies.

Consumer decisions are made based on retail electricity prices, which have not seen the same decreases as wholesale electricity prices. Figure 1 depicts the correlation between average retail electricity prices and average renewable electricity share, average retail electricity price increases as the average RES-E share increases. Numerous renewable policies are financed by levees, increasing the consumer price. The electricity price to end-users comprises of energy – which is 43% of the total price in Europe 2012-, distribution (30%), energy tax (13%) and value-added tax (14%). As a result of increased retail prices and decreasing cost of rooftop solar PV, household self-consumer or behind-the-meter electricity generation is increasing ultimately resulting in an implicit feed-in-tariff. However, this does not eliminate the need for meter generation. Inefficiencies within the retail price, such as "tariff structure, taxation and the lack of time-varying options" give incorrect price signals to the consumer. Producers are encouraged to disclose the cost structure more openly depicting the actual value of the product to consumers (IEA, 2016).

The purpose of this study is to examine the effect of the continuously increasing share of Renewable Energy Sources (RES) in the energy mix on retail electricity prices in 34 OECD countries for 1997 to 2015, considering the change in electricity market structure for the 23 EU countries. The study offers a contribution to the literature by including a sample with more countries than Moreno, López and García-Álvarez (2012) broadening the country group from European Union (EU) countries to include OECD countries as only EU countries fall under the emission trading scheme (EU- ETS). The study uses a more recent dataset (up to 2015), and hence makes a contribution by including: 1) the last decade's developments in renewable energy technology and its consequences to cost and prices of RE, and 2) the global financial crisis and its aftermath, allows us to view the subsequent constraints on investment.

Section 2 analyzes the current OECD electricity market and renewable policies, providing background to the issue at hand, followed by a detailed literature review in section 3. Section 4 discusses the panel data techniques employed to estimate the model. To do so, we will test for the presence of unit roots, if

the results of the test conclude on a stationarity series, a pooled estimation will follow. Alternatively, Pedroni’s (1999, 2004) panel cointegration test, which allows for “heterogenous short-run dynamics” will be pursued. We discuss the estimation results, followed by concluding remarks and a discussion in section 5.

2 Literature review

Previous literature is inconclusive over the effect of the renewable energy share in the energy mix on retail electricity price, as country-specific regulatory policy and market structure has a significant impact on retail electricity prices (Trujillo-Baute, del Río, and Mir-Artigues, 2018). Ballester and Furió (2015) found that in the Spanish case, an increasing share of renewable energy results in lower retail electricity prices for the period 2010 to 2013 if they consider “peak and off-peak prices” separately. The opposite is true for the period 2002 to 2009, due to less intense employment of renewable technologies and higher price associated with these technologies during this period. The weight of RES increased from 29% to 59% from 2008 to 2013, consisting of up to 80% of the daily supply on occasion since 2011. The authors employed a model adapted by Cartea and Figueroa (2005) which is a “stochastic process with mean reversion that includes a discrete jump process” which allows for price volatility to be captured. They arrived at the conclusion that the relationship between the RES-E share and electricity prices is only significant for peak prices; significant positive relationships between thermal (coal and oil-gas), nuclear, hydroelectric, pumping hydroelectric, combined cycle, renewables and price volatility have been found; renewables are negatively correlated with upward jumps in peak prices and no significant relationship have been found considering off-peak prices.

Würtzburg, Labandeiria and Linares (2013) amongst others (Sensfuß, Ragwitz, and Genoese, 2008; Gelabert, Labandeira and Linares, 2011; Sáenz de Miera, del Río and Vizcaíno, 2008) studied the merit-order effect of the renewable energy share on wholesale electricity prices. Würtzburg et al. (2013) thoroughly reviewed previous literature, which allowed them to isolate trends and patterns. They found that the merit-order effect is much larger for smaller markets opposed to larger markets. Conducting an empirical analysis, they found that for each GWh of average hourly predicted renewable energy generation the day-ahead electricity price was reduced by 2% for the German-Austrian market. Their results are in line with simulation-based approaches. This price effect is not directedly transferred to the consumer retail price. The authors found that Germany’s withdrawal from nuclear energy did not affect the merit order effect. They found weak evidence supporting string merit-order effects for high electricity demand, possibly due to the use of fossil fuels during these periods. Sañenz de Miera et al. (2008) states that this decrease in marginal cost to the producer may offset the initial setup cost and act as an incentive to invest in renewable technologies.

Atems and Hotaling (2018) examine the effects of renewable and non-renewable

electricity on economic growth for a panel of 174 countries for the period 1980 to 2012 while controlling for education, trade, government expenditure along with other social indicators known to affect growth. The methodology consisted of a comparison between OLS, Fixed effects, baseline system GMM, two-step GMM, and alternative system GMM approaches for robustness. The coefficients of the control-variables of the two-step GMM approach is consistent with previous literature. The results conclude that both renewables and non-renewables are positively correlated with economic growth at a 5% level of significance, while the inefficiency of the electricity grid is shown to have a significant negative relationship. As such, developing countries can address climate change by introducing renewable energy sources into the energy mix without concern of deterring economic growth as long as the proper policies are in place. Tampakis et al. (2017) found that renewables energy is appropriate for ensuring energy security in isolated areas as well as having significant impacts on energy balances and environmental protection.

Imura and Cross (2018) analyze the effects of renewable energy on household electricity prices in liberalized electricity markets in 7 OECD countries. The results indicate a “strong path dependency” for household electricity prices, while market reforms resulted in more significant price decreases than policy anticipated. There is no significant relationship between higher prices and increased renewable deployment. The authors suggest that renewables are more likely to be traded with neighboring countries than deployed by the host country due to the merit-order effect.

This study’s approach aligned with the research conducted by Moreno, López and García-Álvarez (2012) who developed an econometric panel data model to estimate this relationship for the European Union from 1998 to 2009. They performed the Hausman test to see if fixed effects or random effects are more appropriate and concluded on fixed effects to control for country-specific policy. They found that a 1% increase in renewable energy results in a 0.018% increase in household electricity prices. Noting that while the effect is small, it mostly influenced by “RES-E support schemes financed by the electricity market.” Public RES-E support schemes may effectively mitigate the retail price increase, which has been limited to what is deemed truly necessary (European Commission, 2015). Our research builds on that of Moreno et al. (2012) to see if the degree and magnitude of the effect of renewable energy on household electricity prices are similar for 1997 to 2015 than it was for 1998 to 2009. Improvements in technology, increased competition and “a large base of experienced, internationally active project developers” have been singled out as key drivers in the cost reduction of renewable technologies (IRENA, 2018). Could the effect of the reduction of public RES-E support schemes on household electricity prices be offset by the decreased price of renewable technologies?

3 Methodology and Data

3.1 Theoretical Framework

This study’s methodology is based on one of the models employed by Moreno, López, and García-Álvarez (2012). Our model is defined in equation (1), where electricity generated from renewable sources as a percentage of total gross electricity production ($RESE$), gross domestic product per capita, measured in constant 2010 US dollars ($GDPPC$), greenhouse gas emissions by the energy sector as a percentage of total greenhouse gas emissions (EIE), energy dependency (ED), and the market share of the largest electricity generator (EGC) are determinants of retail electricity prices:

$$\ln(y_{i,t}) = \alpha_i + \beta_1 \ln(RESE_{it}) + \beta_2 \ln(GDPPC_{it}) + \beta_3 \ln(EIE_{it}) + \beta_4 ED_{it} + \beta_5 \ln(EGC_{it}) + u_{it} \quad (1)$$

$RES-E$ provides information regarding the share of renewable energy sources employed. Theory suggests that a positive relationship exists as public support schemes fund projects. The impact of $RES-E$ on electricity prices is important given the reduction of public support schemes. Historically the price associated with employing renewable technologies has been high when compared to the price of traditional fossil fuel energy sources. Moreno et al. (2012) found that a 1% increase in $RES-E$ led to a 0.018 percent increase in household electricity prices at a 1% level of significance. $GDPPC$ provides a measurement of relative economic activity for each country and will act as a demand proxy capturing the structure and level of economic development. A positive relationship is expected between a higher level of $GDPPC$ and retail electricity prices, this is aligned with the findings of Moreno et al. (2012) of a significant 1.345 percent increase. EIE is included as EU countries engage in an Emissions trading scheme, fluctuations in this variable have a direct effect on the marginal cost of energy production, as such we expect to see a positive relationship, as with Moreno et al. with a 0.025 significant parameter estimate. ED indicates the degree to which the countries are dependent on energy imports which are linked to the price of natural resources and therefore links to the price of electricity. The European Union is highly dependent on energy imports, although ED is expected to yield a negative impact as EU policy aims to increase electricity imports between member states in an attempt to reduce electricity prices (Hyland, 2016). This is contradictory to the findings of Moreno et al. where a 1% increase ED leads to a 0.004 percent increase in electricity prices. EGC (Electricity Generation Concentration) measures the market share of the largest electricity generator in the market, therefore an increase in this variable would indicate a reduction in competition. Theory suggests that positive relationship should exist, as an increase in market share infers higher prices. However, Hattori et al. (2004) and Nagayama (2009) found that this was not the case, as a loss of economies vertical integration occurs. Both these studies support the findings of Moreno et al. of a significant negative relationship of a 1% increase in EGC leading to a 0.005 percent reduction in electricity prices.

3.2 *Econometric methodology*

The Im, Pesaran, and Shin (2003) panel unit root test is used to confirm stationary variables, the test allows for heterogeneous autoregressive coefficients. Apergis and Payne (2010) and Inglesi-Lotz (2016) indicate that the equation used to test for a common unit root is:

$$y_{it} = \rho_i Y_{it-1} + \delta X_{it} + \varepsilon_{it} \quad (2)$$

Where $i=1, \dots, N$ for each country in the data span; $t=1, \dots, T$ is the year; X_{it} represents the combined exogenous variables including two way fixed effects; ρ_i depicts the autoregressive coefficients and ε_{it} the disturbance term. Apergis and Payne (2010), and Inglesi-Lotz (2016) explain that Im et al. (2003) uses “the average of the Augmented Dickey-Fuller unit root test while allowing for different orders of serial correlation:”

$$\varepsilon_{it} = \sum_{j=1}^{p=1} \varphi_{ij} \varepsilon_{it-j} + u_{it} \quad (3)$$

Substitution (2) into (1):

$$y_{it} = \rho_i Y_{it-1} + \sum_{j=1}^{p=1} \varphi_{ij} \varepsilon_{it-j} + \delta X_{it} + u_{it} \quad (4)$$

Where ρ_i now indicates the number of lags and the null and alternative hypothesis is as follows:

$$H_0 : \text{Panel contains a unit root}$$

$$H_1 : \text{Panel is stationary}$$

To ensure robustness of the unit root test results, we also conducted the Levin, Lin and Chu t-statistics, the Breitung t-statistic, the Im, Pesaran and Shin W-statistic, the ADF Fisher Chi-square, and the PP Fisher Chi-square test. If we reject the null hypothesis, therefore concluding on a stationary series, we will proceed with a pooled estimation. If not, we have to proceed with Pedroni’s (1999, 2004) panel cointegration test which allows for cross-country interconnections.

$$y_{it} = \alpha_i + \delta_i t + \gamma_{1i} \ln(RESE_{it}) + \gamma_{2i} \ln(GDPPC_{it}) + \gamma_{3i} \ln(EIE_{it}) + \gamma_{4i} ED_{it} + \gamma_{5i} \ln(EGC_{it}) + \varepsilon_{it} \quad (5)$$

Where $i = 1, \dots, N$ for each country in the data span; $t=1, \dots, T$ is the year; α_i and δ_i represents country-specific time-invariant effects, and ε_{it} represents the estimated residuals deviations from the long-run value. Where,

$$H_0 : \text{Panel exhibits no cointegration}$$

$$H_1 : \text{Panel is cointegrated}$$

And the unit root test,

$$\varepsilon_{it} = \rho_i \varepsilon_{it-1} + w_{it} \quad (6)$$

Pedroni (1999, 2004) make use of four statistics: panel ν , panel ρ , panel PP and panel ADF-statistic. Large positive values signify rejection in the panel ν statistic, where larger negative values indicate rejection in panel ρ , panel PP and panel ADF-statistic. “These statistics allow for heterogeneous fixed effects and deterministic trends and also for heterogeneous short-run dynamics.” Pedroni (1999, 2004) found that panels with T=20 the ADF group and ADF panel statistic, followed by the panel ρ statistic generally fair the best concerning power, size, and reliability, while the panel and group PP are somewhere between the ADF panel and panel ρ statistic.

If we reject the null hypothesis of no cointegration with the Pedroni test, the Hausman test will be conducted to conclude whether a pooled or fixed effects estimation will follow. If the Hausman test concludes on a fixed effects model, we will proceed with a two-way fixed effects estimation, since we assume that each country and year has specific and unique time-invariant characteristics that influence the significant differences in household electricity prices amongst the 34-OECD countries. As such we control for the assumed correlation between the error term and our explanatory variables, this is denoted by α_i and is treated as a regression parameter (Wooldridge, 2015).

3.3 Dataset

The data utilized in this evaluation were obtained from the International Energy Agency (EIA), the World Bank, OECD and Eurostat databases (the source of each indicator is described in Table 1, last column). Since data availability for wholesale electricity prices is restricted, only retail electricity prices will be examined from 1997-2015. Data availability for electricity price is not reported for the entire data span, and EGC is only available for EU countries (1997-2015), leading to an unbalanced panel dataset. The dependent variable is retail electricity prices in index form along with renewable energy share, electricity generation concentration, GDP per capita, energy industry emissions and energy dependence as explanatory variables.

4 Empirical results

As discussed in the Methodology section the unit root test proposed by Im, Pesaran, and Shin (2003) was done to determine the stationarity of the variables. In each case (except for $\ln(\text{EGC})$ and $\ln(\text{GDPPC})$ regarding trend and intercept) the null hypothesis was accepted, as such, each series in the panel dataset contains a unit root and is non-stationary as shown in Table 4 (see Appendix). Given the results, we proceeded by testing for the existence of cointegration; results are represented in Table 2. Where each model has $\ln(\text{Retail Price})$ as the dependent variable followed by the following explanatory variables: Model (1) $\ln(\text{RES-E})$; Model (2) $\ln(\text{RES-E})$, $\ln(\text{GDPPC})$; Model (3) $\ln(\text{RES-E})$, $\ln(\text{GDPPC})$, and $\ln(\text{EIE})$; Model (4) $\ln(\text{RES-E})$, $\ln(\text{GDPPC})$, $\ln(\text{EIE})$ and ED ; Model (5) $\ln(\text{RES-E})$, $\ln(\text{GDPPC})$, $\ln(\text{EIE})$, ED , and $\ln(\text{EGC})$. Inglesi-Lotz

(2016) explains that these statistics “are based on the average values of the individual autoregressive coefficients linked with the unit root test for each country in the panel.” Within all deterministic structures, the PP-statistics indicates the rejection of the null hypothesis of no cointegration at a 1% level of significance. As such, the results confirm a long-run relationship between retail electricity prices and electricity generated from renewable sources, including the control variables such as market share for the 34 OECD countries. Given the results of the Hausman test, a two-way fixed effects estimation followed (Table 3), to account for heterogeneity between cross- and year-sections while seeing the effects of each control variable as our number of cross-sections change significantly when controlling for market structure.

Model (1), (2) and (3) all have positive and statistically significant coefficients for RES-E, indicating that electricity generated from renewable sources does have a significant effect on retail electricity prices when controlling for GDP per capita, and energy industry emissions. Once we include energy dependence in model (4), the coefficient for RES-E remains positive but is not statistically significant in the 34 OECD countries.

Staying true to Moreno et al. (2012), the results indicate the need to control for electricity generation market share, represented by model (5). Model (5) reduces our number of cross-sections from 34 to 23 since the data for EGC is only available for EU countries. The variables expressed in natural logarithms can be expressed in terms of elasticities. We see that all variables are statistically significant, except for ED, of which the sign is consistent with expectations. A 1% increase in the share of RES-E results in a 0.046% increase in the share of retail electricity prices, the coefficient is slightly large than Moreno et al. (2012). A 1% increase in GDP per capita leads to a 0.429% increase in retail electricity prices, while a 1% increase in EIE leads to 0.157% increase. The effect of EIE is much larger than in Moreno et al. (2012), indicating that the effect of emission trading schemes increased from 2007 to 2015. EIE does not have a significant effect in Model (4) which contains the OECD countries of which not everyone has a emissions trading scheme in contrast to Model (5) which contains only EU countries all employing a emissions trading scheme. ED has a negative sign, illustrating that more countries have become energy exporters, but is not statistically significant. A 1% increase in EGC leads to a 0.091% decrease in retail electricity prices, indicating that increased market power led to a price reduction contradictory to perfect competition theory, but in line with the findings of Moreno et al. (2012) as they explained that countries with higher market concentration have more government subsidies decreasing electricity prices. All the results except for ED are in line with that of Moreno et al. (2012).

5 Conclusion and Policy Implications

The purpose of this paper is to determine the effect of the increasing renewable electricity share on retail electricity prices for 34-OECD countries, considering

the change in market structure for 23 EU countries in a panel data framework from 1997 to 2015. The results hold important implications for future policies encouraging renewable energy sources and understanding price signals as a consumer. The analysis employed unit root test to confirm the univariate characteristics of the series, which concluded on non-stationarity. Furthermore, the Pedroni panel cointegration test confirmed the existence of a long-run relationship between retail electricity price, the share of renewable electricity formation, GDP per capita, greenhouse gas emissions by the energy sector, energy dependence and electricity market concentration.

The two-way fixed effects estimation results suggest that an increase in the share of renewable energy led to an increase in retail electricity prices while an increase in electricity market concentration to a decrease in electricity prices, *ceteris paribus*, confirming a priori expectations.

The current increase of RES-E on electricity prices is marginal and is largely due to “RES-E support schemes financed by the electricity market” (Moreno et al., 2012). IRENA (2018) projected that renewable energy sources would be price competitive with fossil fuels within the next two years, we suspect that with future data the relationship will eventually be negative. Encouraging private RES-E support schemes could effectively mitigating the increases in retail electricity prices bringing about this relationship sooner. As RES-E support schemes increased the renewable generation capacity and further increases in the share of RES-E could bring about price reductions. Emissions trading schemes by the energy industries only hold a significant effect for EU countries. Most countries’ energy dependency changed over the period, declining in both energy exports and imports (Dedeoğlu and Kaya, 2013) and holds no significant effects for retail electricity prices in this analysis. Majority of these findings support the results of Moreno et al (2018). However, our coefficient for Energy Dependency is negative and statistically insignificant where that of Moreno et al. (2012) was positive and significant. As mentioned before this could be the result of EU policy encouraging energy imports between member countries.

The role of clean energy sources toward global decarbonisation is inescapable in reaching climate goals. Therefore, the results hold important implications for future policies encouraging renewable energy sources and understanding price signals as a consumer. Strengthening renewable electricity generation could shield against threats to electricity security, as well as providing efficient and affordable access to electricity aligned with Sustainable Development Goal 7. Consumers should benefit directly through future price reductions as well as through environmental improvement regarding air quality etc. Renewable energy sources require effective supply and demand matching, encouraging investment while phasing out support schemes in the long-run . The electricity market and regulatory framework need to be adjusted to accommodate flexible responses from the network to compensate for renewable intermittency (IAE, 2016). Increases in electricity prices to reflect the social cost towards the consumer should act as signal to move towards cleaner energies, as the marginal cost associated is low while the environmental benefit is high.
